Abstract. We calculated a grid of evolutionary models for white dwarfs with helium cores (He-WDs) and investigated the occurrence of hydrogen-shell flashes due to unstable hydrogen burning via CNO cycling. Our calculations show that such thermal instabilities are restricted to a certain mass range ($M \approx 0.21 \dots 0.30 M_{\odot}$), consistent with earlier studies. Models within this mass range undergo the more hydrogen shell flashes the less massive they are. This is caused by the strong dependence of the envelope mass on the white dwarf core mass. The maximum luminosities from hydrogen burning during the flashes are of the order of $10^5 L_{\odot}$. Because of the development of a pulse-driven convection zone whose upper boundary temporarily reaches the surface layers, the envelope's hydrogen content decreases by $\Delta X \approx 0.06$ per flash.

Our study further shows that an additional high mass-loss episode during a flash-driven Roche lobe overflow to the white dwarf's companion does not affect the final cooling behaviour of the models. Independent of hydrogen shell flashes the evolution along the final white dwarf cooling branch is determined by hydrogen burning via pp-reactions down to effective temperatures as low as ≈ 8000 K.

Key words: Stars: evolution – Stars: interiors – white dwarfs – Binaries: general –

1. Introduction

In Driebe et al. (1998) (hereafter referred to as Paper I) we presented a grid of evolutionary tracks for low-mass white dwarfs with helium cores (He-WDs) in the mass range from 0.179 to $0.414 M_{\odot}$. The lower masses allow applications to companions of millisecond pulsars. As an example we derived a cooling age for the He-WD companion of the millisecond pulsar PSR J1012+5307 of ~ 6 Gyr, which is in good agreement with the pulsar's spin-down age of ~ 7 Gyr. The evolutionary tracks

Send offprint requests to: T. Driebe

are based on a $1 M_{\odot}$ model sequence extending from the pre-main sequence stage through the red-giant branch (RGB) domain. We forced the models to move off the giant branch and to evolve into the white dwarf regime by applying large mass-loss rates at appropriate positions to take into account the binary nature of He-WDs (for details see Paper I).

As pointed out in Paper I one of the major results of our study was the dominant contribution of hydrogen burning to the luminosity budget of the He-WDs. Therefore the final cooling evolution is slowed down, and the derived cooling ages are notably larger than those found in models which do not consider nuclear burning or do not find hydrogen burning to be important due to much lower envelope masses.

In the present paper we will discuss the evolution of sequences which undergo hydrogen shell flashes in detail. It is organized as follows: In Sect. 2.1 we will briefly summarize the main reasons for unstable nuclear burning, and report in Sect. 2.2 on former studies concerning instabilities in He-WDs. In Sect. 3 we describe the evolutionary code used for our calculations. The main results of the calculations are discussed in Sects. 4.1 to 4.4. Finally, conclusions are given in Sect. 5.

2. Unstable nuclear burning

2.1. The two general cases

There are two reasons for nuclear burning to become unstable: The first one is the decoupling of the thermal and mechanical structure of a star due to large electron degeneracy. If the equation of state gets more and more independent of the temperature a local increase in energy production cannot be stabilized by a local expansion with following cooling of the affected layers. Therefore a further increase in energy production will lead to a corresponding increase in temperature which in turn will again raise the energy release. This phase of thermally unstable burning will continue until the ongoing temperature increase results in an effective lifting of degeneracy in the burning zone. The stronger coupling of thermal and mechanical structure will

then allow for an expansion and the transition to a phase of stable nuclear burning. This kind of instability is found, for instance, during the onset of central helium burning in low-mass stars ($M_{\text{initial}} \lesssim 2 M_{\odot}$, $M_{\text{core}} \approx 0.47 M_{\odot}$ for $Z = 0.02$) on the tip of the red giant branch (central helium flash).

The second reason for thermally unstable nuclear burning is mostly based on the geometry of the burning region and occurs only during shell burning. If the shell's mass (its "thickness") becomes too small compared to its radial extent, the expansion following a local increase in temperature and energy production is insufficient to cool the shell: The thin burning zone will instead be heated by expansion, and the energy production is further increased. The thermal runaway only stops when the thickness of the shell is large enough as to allow for a cooling expansion. This kind of unstable burning repeatedly takes place during the double shell-burning phase of AGB stars (Schwarzschild & Härm 1965, Weigert 1966). There, these instabilities are known as thermal pulses or helium shell flashes caused by thermally unstable helium burning.

Schwarzschild & Härm (1965) derived an instability criterion for non-degenerate matter by linear perturbation analysis. This criterion includes the shell thickness as well as the temperature exponent ν of the energy generation rate ($\epsilon \propto T^{\nu}$) as a measure of the temperature dependence of nuclear burning. The assumption of non-degeneracy is justified for the helium layers of AGB models during most of the thermal pulse evolution. According to the Schwarzschild & Härm criterion unstable burning is favored when the shell becomes thinner and the burning is quite temperature sensitive, as it is the case for helium burning. A similar criterion for the study of thermal pulses was derived by Sackmann (1977). In a recent study Frost et al. (1998) report that in advanced stages of thermal pulse evolution degeneracy in the region of the helium burning shell may become noticeable and can therefore lead to significantly stronger pulses (degenerate pulses). Kippenhahn & Weigert (1990) give an instability criterion which also takes degeneracy into account.

2.2. Unstable burning in helium white dwarfs

Unlike as in AGB stars, where the helium burning shell becomes thermally unstable, He-WDs show instabilities related to CNO cycling which dominates hydrogen burning in the lower, i.e. hotter part of the geometrically thin shell.

Kippenhahn et al. (1967) calculated a He-WD model with $M = 0.264 M_{\odot}$ which evolves through a phase of unstable burning. As a result the track in the Hertzsprung-Russell diagram (HRD) is reversed and the He-WD returns to the RGB domain. The evolution of the white dwarf during the thermal instability was followed in more detail by Kippenhahn et al. (1968). Giannone et al. (1970) found unstable burning in a $0.268 M_{\odot}$ He-WD model, whereas their models with $M = 0.366 M_{\odot}$ and $0.426 M_{\odot}$ did not show any sign of thermal instabilities. Unlike the previously mentioned studies, Webbink (1975) found only small hook-like excursions in his He-WD tracks close to the point of maximum effective temperature.

Iben & Tutukov (1986) calculated a $0.298 M_{\odot}$ He-WD model based on a $1 M_{\odot}$ model which suffered from high mass loss episodes on the RGB, mimicking Roche-lobe overflow to a companion. They found two strong thermal instabilities to occur on the cooling branch resulting in a track similar to the one of Kippenhahn et al. (1968).

Castellani et al. (1994) calculated a grid of He-WD model sequences for different metallicities Z using the same technique as Iben & Tutukov (1986). Like Giannone et al. (1970) they found thermal instabilities only below a certain mass limit which depends on Z : For $Z = 0.01$ and 0.001 no flashes were found for $M \gtrsim 0.33 M_{\odot}$ and $M \gtrsim 0.35 M_{\odot}$, respectively. For $Z = 2 \cdot 10^{-4}$ one hydrogen shell flash was found for $M = 0.370 M_{\odot}$ and $M = 0.389 M_{\odot}$. In a recent study Sarna et al. (1998) found instabilities in their cooling tracks for $M < 0.2 M_{\odot}$, quite similar to those of Webbink (1975) who, however, used rather large time steps.

Due to large time steps and/or significantly smaller envelope masses several studies did not find thermal instabilities at all during the cooling of He-WDs, as e. g. Chin & Stothers (1971), Alberts et al. (1996), Althaus & Benvenuto (1997), Benvenuto & Althaus (1998) and Hansen & Phinney (1998).

3. The evolutionary calculations

Besides some minor modifications we used the evolutionary code described by Blöcker (1995). Nuclear burning is accounted for via a nucleosynthesis network including 30 isotopes with all important reactions up to carbon burning similar as in El Eid (1994). The most recent radiative opacities by Iglesias et al. (1992) and Iglesias & Rogers (1996), supplemented by those of Alexander & Ferguson (1994) in the low-temperature region, are employed. Diffusion is not considered. The initial composition is $(Y, Z) = (0.28, 0.02)$, the mixing length parameter $\alpha = 1.7$ followed from calibrating a solar model. The Coulomb corrections to the equation of state are those given by Slattery et al. (1982).

He-WDs are known to be components in binary systems where early case B mass transfer (Kippenhahn & Weigert 1967) must have taken place during RGB evolution which forces the stars to leave the RGB before the onset of helium burning and to evolve into the white dwarf regime. We did not calculate the mass exchange phases during the RGB evolution in detail because we are primarily interested in the cooling properties of the white dwarf models themselves rather than in the generation of these models by binary star evolution. Hence we used an approximate approach to get the pre-white dwarf models (see also Iben & Tutukov 1986, Castellani et al. 1994, and Paper I):

We calculated a $1 M_{\odot}$ sequence from the pre-main sequence phase up to the tip of the RGB. Along the RGB we applied mass-loss rates \dot{M}_R according to Reimers (1975) with $\eta = 0.5$. At appropriate positions high mass loss rates, \dot{M}_{high} , were invoked in order to get models of desired final mass, M : $0.179, 0.195, 0.234, 0.259, 0.300, 0.331$ and $0.414 M_{\odot}$. Figure 1 displays all He-WD sequences in the HRD. High mass

Fig. 1. Hertzsprung-Russell diagram with evolutionary tracks for He-WD models. The tracks with solid lines belong to final white dwarf masses of 0.179, 0.195, 0.234, 0.259, 0.300, 0.331 and 0.414 M_{\odot} (from top to bottom). The dotted lines show the flash phases for $M = 0.234$ and $0.259 M_{\odot}$, the dashed line gives the $1M_{\odot}$ evolutionary path the He-WD models are based upon.

loss varied from $\dot{M}_{\text{high}} \approx 10^{-9} M_{\odot} \text{ yr}^{-1}$ for $M \approx 0.15 M_{\odot}$ to about $10^{-6} M_{\odot} \text{ yr}^{-1}$ for $M \approx 0.4 M_{\odot}$. These values were chosen to allow the models to hold thermal equilibrium during their further evolution (with $\dot{M} = \dot{M}_{\text{high}}$). For a more detailed description we refer to Paper I. Here, we only want to stress the importance of sufficiently small time steps when the evolution through thermal instabilities should be followed properly. A brief discussion on this topic is given in the Appendix.

4. Results

4.1. General remarks

We briefly repeat the main results of our calculations which have been addressed in detail in Paper I. Due to the comparatively large remaining envelope masses after termination of the RGB evolution (see Table 1¹) one of the main characteristics of our white dwarf models is that hydrogen burning due to pp-reactions remains the main energy source down to effec-

¹ We note that the same table is shown in Paper I but the data for $M = 0.179$ and $0.195 M_{\odot}$ did not refer to $T_{\text{eff}} = 10000 \text{ K}$ as indicated in the caption but erroneously to $T_{\text{eff}} = 5000 \text{ K}$ as for the larger masses.

Table 1. Total remnant mass M , mass of the hydrogen-exhausted core M_c , total mass of the outer hydrogen layers ("thickness") M_H , envelope mass M_{env} , and helium surface abundance by mass fraction Y , at $T_{\text{eff}} = 5000 \text{ K}$ for $M > 0.2M_{\odot}$ and at 10000 K for $M \leq 0.2M_{\odot}$ after the end of RGB evolution. M_c is defined by the mass coordinate below which $X \leq 0.35$ with X being the mass fraction of hydrogen.

M/M_{\odot}	M_c/M_{\odot}	$\frac{M_H}{10^{-3}M_{\odot}}$	$\frac{M_{\text{env}}}{10^{-3}M_{\odot}}$	Y
0.179	0.1693	5.061	10.211	0.464
0.195	0.1859	4.937	9.598	0.461
0.234	0.2220	8.118	13.098	0.354
0.259	0.2524	4.771	7.232	0.312
0.300	0.2960	3.189	4.746	0.301
0.331	0.3281	2.509	3.744	0.301
0.414	0.4116	1.446	2.175	0.301

tive temperatures well below 10^4 K (see Paper I and Fig. 2). This residual burning leads to a significant slow-down of the further evolution, resulting in larger cooling ages (typically a few 10^9 yr , see Fig. 3) than found for He-WD models where hydrogen burning is negligible due to smaller, ad-hoc assumed ² envelope masses, or even not considered at all. The implications of evolutionary envelope masses for the evolution of white dwarfs are discussed in Blöcker et al. (1997).

Fig. 2. Ratio of hydrogen (L_{Hyd}) to gravothermal luminosity (L_g) as a function of T_{eff} for He-WDs of different masses (in M_{\odot}). For the sequences which undergo hydrogen flashes only the final evolution along the cooling branch is shown.

Besides of this important property of He-WDs and its consequence for age determinations of, e.g., millisecond pulsar systems as PSR J1012+5307 (cf. Paper I), another result of our study concerns the occurrence of hydrogen shell flashes:

² In these calculations the envelope mass is taken as a free parameter and has not been computed from the mass-loss history of the He-WD progenitor according to the binary nature of He-WDs.

Fig. 3. Same as Fig. 2, but as a function of $t_{\text{post-RGB}}$. The age at the very left of the diagram corresponds to effective temperatures of about $T_{\text{eff}} \approx 15000 \dots 18000$ K, the curves end at temperatures of $T_{\text{eff}} \approx 4000 \dots 5000$ K. We adopted $t = 0$ when the models pass $T_{\text{eff}} = 10000$ K for $M < 0.2 M_{\odot}$ and $T_{\text{eff}} = 5000$ K for $M > 0.2 M_{\odot}$ after leaving the RGB.

We did not find any unstable hydrogen-burning in the sequences with masses $M = 0.179, 0.195$ and $0.414 M_{\odot}$. Only for $M = 0.234$ and $0.259 M_{\odot}$ major hydrogen shell flashes ($L_{\text{Hyd,max}} \gtrsim 10^5 L_{\odot}$) developed with concomitant extended loops in the HRD. Only a temporal slight increase of the CNO-luminosity on the cooling branch was found in the sequences with $M = 0.300$ and $0.331 M_{\odot}$.

The restricted mass range for the occurrence of hydrogen flashes agrees with earlier results, e.g. Kippenhahn et al. (1968), Giammona et al. (1970) or Castellani et al. (1994). We note that Webbink (1975) suggested a lower mass limit of $M \approx 0.206 M_{\odot}$, in good agreement to our findings. The $0.298 M_{\odot}$ model of Iben & Tutukov (1986) is fully unstable, our $0.300 M_{\odot}$ model only marginally. The calculations of Castellani et al. (1994) suggest that the upper boundary for the flash range is higher for lower metallicity. Therefore, their result of $M_{\text{upper}}^{\text{flash}} < 0.33 M_{\odot}$ for $Z = 0.01$ is consistent with our calculations. Complementary calculations where equilibrium rates for the pp-chains and the CNO-cycle were used instead of the nuclear network show three hydrogen shell flashes for $M = 0.227 M_{\odot}$ and one strong hydrogen shell flash for $M = 0.310 M_{\odot}$. Because we found no hydrogen flashes in our standard sequences with $M = 0.300 M_{\odot}$ and $M = 0.195 M_{\odot}$ we conclude that the mass range for the occurrence of instabilities depends on uncertainties due to different input physics (e.g. diffusion as in Iben & Tutukov (1986)), and that the boundaries $M_{\text{lower}}^{\text{flash}} = 0.21 M_{\odot}$ and $M_{\text{upper}}^{\text{flash}} = 0.30 M_{\odot}$ may be uncertain by about $0.01 M_{\odot}$.

According to our calculations the number of hydrogen flashes depends on the mass: We found one major hydrogen flash for $M \gtrsim 0.25 M_{\odot}$, two flashes for $0.25 \gtrsim M/M_{\odot} \gtrsim 0.23$ and three flashes for $0.23 \gtrsim M/M_{\odot} \gtrsim 0.21$. Thus, we conclude that unstable hydrogen burning in He-WDs caused

by the fading CNO cycling (see next section) is restricted to a certain mass range of $M \approx 0.21 \dots 0.30 M_{\odot}$. Furthermore, the number of flashes increases with decreasing white dwarf mass.

It is noteworthy that the cooling properties below $T_{\text{eff}} \lesssim 20000$ K are independent on the occurrence of hydrogen shell flashes during the previous evolution. Hydrogen burning remains the main energy source along the cooling branch down to very low effective temperatures (see Sect. 4.3). Because He-WDs suffering from hydrogen flashes evolve back to the RGB regime one has to account for high mass-loss episodes due to Roche lobe overflow although the time spent away from the cooling branch is small compared to the cooling time itself. Our calculations show that the cooling is not affected by such high mass-loss episodes (see Sect. 4.4).

4.2. The main flashes

Figures 4 and 5 show the complete evolutionary tracks for the sequences with $M = 0.234 M_{\odot}$ and $0.259 M_{\odot}$. While the evo-

Fig. 4. HRD with a complete evolutionary track for the He-WD sequence with $M = 0.234 M_{\odot}$. The dashed line shows the $1 M_{\odot}$ track which was used to generate the post-RGB model. Two main flashes occurred, each followed by weaker subflashes (see also Fig. 8).

lution of the $M = 0.259 M_{\odot}$ model is characterized by only one major flash resulting in an extended loop in the HRD (see Fig. 5), the model with $M = 0.234 M_{\odot}$ experiences two strong flashes (see Fig. 4).

After mass loss terminates the RGB evolution, the remnants evolve at almost constant surface luminosity to higher effective temperatures towards the white dwarf cooling branch. In this

Fig. 5. Same as Fig. 4, but for the $M = 0.259 M_{\odot}$ sequence. Here only one major flash was found. Properties of the models labeled by capital letters are given in Tab. 2.

Table 2. Data for the marked points in Fig. 5. The age was set to zero at $T_{\text{eff}} = 10000$ K of the post-RGB evolution. The different evolutionary stages A-G are discussed in the text.

Model	$t_{\text{post-RGB}}/10^7$ yr	$\log(T_{\text{eff}}/\text{K})$	$\log(L/L_{\odot})$
A	1.469119	4.2865	-0.5726
B	2.803540	4.3678	-0.0754
C	2.803641	3.9532	-1.4070
D	2.803643	3.8488	-1.0786
E	2.803658	3.8413	-0.2007
F	2.803744	4.3272	2.0633
G	13.003598	4.2859	-0.8025

phase the total luminosity is almost entirely supplied by nuclear burning due to CNO cycling ($L \approx L_{\text{CNO}}$). The contribution due to contraction is negligible. The situation changes when the star reaches the cooling branch. Now, the temperature within the hydrogen burning shell becomes too low to support further CNO cycling. L_{CNO} drops significantly, and contraction sets in until pp-burning takes over the main nuclear energy production. Still $L_{\text{Hyd}} \gg L_g$ holds in this early cooling period (see e.g. Fig. 11 and Fig. 5 in Paper I). The phase of unstable burning starts at typical effective temperatures of $T_{\text{eff}} \approx 20000 \dots 25000$ K on the cooling branch (close to point A in Fig. 5). At this stage of evolution the energy production due to CNO cycling rises again and finally exceeds the pp-contribution by large amounts. In Fig. 5 this part roughly coincides with the loop between point A and B in the HRD. The duration for this period of evolution (Δt_{onset}) depends on the remaining en-

velope mass and the thermal timescale of the burning shell, and ranges from $\Delta t_{\text{onset}} \approx 4 \cdot 10^6$ yr for $M \approx 0.23 M_{\odot}$ to $\Delta t_{\text{onset}} \approx 4 \cdot 10^7$ yr for $M \approx 0.30 M_{\odot}$. For example, the model with $M = 0.259 M_{\odot}$ gives $\Delta t_{\text{onset}} \approx 1.7 \cdot 10^7$ yr, that with $M = 0.234 M_{\odot}$ only $\Delta t_{\text{onset}} \approx 5 \cdot 10^6$ yr. At the onset of the second flash for $M = 0.234 M_{\odot}$ one gets $\Delta t_{\text{onset}} \approx 1.2 \cdot 10^7$ yr due to the further reduced envelope mass.

The increasing energy release during the flash development causes a steep temperature gradient in the vicinity of maximum energy production and the formation of a pulse-driven convection zone well inside the hydrogen burning shell (beyond point B). The situation is displayed in Fig. 6: At $t \approx 2.80357 \cdot 10^7$ yr

Fig. 6. Development of the pulse-driven convection zone (intermediate grey shaded region) during the hydrogen-flash phase of the $M = 0.259 M_{\odot}$ sequence as a function of time. Point B from Fig. 5 is located at $t \approx 2.80354 \cdot 10^7$ yr. Also shown are the lines of maximum energy generation due to hydrogen burning, ϵ_{max} , the regions where ϵ_{max} has dropped to 1% (dark grey shaded) and 0.1% (light grey shaded) respectively, and the degeneracy parameter ψ (right y-axis) at the point with $\epsilon = \epsilon_{\text{max}}$.

the convective shell establishes right above the locus of maximum energy production due to hydrogen burning. The degeneracy inside the burning shell is quite moderate as can be seen from the degeneracy parameter ψ at maximum energy generation (for the definition of ψ see e.g. Kippenhahn & Weigert 1990). During the onset of the unstable burning, $\psi \approx -0.5 \dots -1$.

Once the convection zone is fully established, the evolution is rapidly accelerated (roughly between point B and D). The typical time scale is now of the order of a few decades. The luminosity contribution due to nuclear burning increases several orders of magnitude and the convection zone grows until it extends to the stellar surface (see Fig. 6, $t \approx 2.80354 \dots 2.80364 \cdot 10^7$ yr). Although L_{Hyd} increases to about $10^5 L_{\odot}$ in this phase (near point C in Fig. 5), the surface luminosity drops by almost 2 orders of magnitude because the increased energy production

is largely overcompensated by the energy loss due to the expansion of the envelope. This expansion roughly doubles the stellar radius and leads to a complete lifting of degeneracy in the shell (sharp drop of ψ). For instance, model B has $R \approx 0.05 R_\odot$, and beyond point C one finds $R \approx 0.1 R_\odot$.

The maximum hydrogen luminosity reached during the flash is supplied by pp-burning, although the onset of the instability is triggered by CNO cycling (see below, Fig. 7). For $M = 0.259 M_\odot$, $L_{\text{Hyd,max}} \approx 1.3 \cdot 10^5 L_\odot$. For $M = 0.234 M_\odot$ both flashes are of comparable strength with $L_{\text{Hyd,max}} \approx 2.7 \cdot 10^5 L_\odot$ for the first and $L_{\text{Hyd,max}} \approx 2.3 \cdot 10^5 L_\odot$ for the second flash. The time span between both flashes amounts to $1.8 \cdot 10^7$ yr (see also Fig. 7).

Beyond point C the most luminous part of the flash instability has passed and L_{Hyd} decreases while L_g increases. The surface luminosity is again enhanced due to the increase of L_g . At point D ($T_{\text{eff}} \approx 7000$ K, see Fig. 5) the upper boundary of the pulse-driven convection zone reaches the surface (at $t \approx 2.80364 \cdot 10^7$ yr in Fig. 6). Due to the convective transport of hydrogen from the surface layers down to the hydrogen burning region the surface hydrogen abundance is reduced by about $\Delta X \approx 0.06$ when surface convection establishes. The small blueward evolution in the evolutionary track close to point D is related to these composition changes in the envelope (see Iben & Tutukov 1986). The compositional change is consistent with the results of the flash model of Kippenhahn et al. (1968) who found $\Delta X \approx 0.08$. Iben & Tutukov (1986) found a larger amount of $\Delta X \approx 0.2$, probably due to their consideration of gravitational and chemical diffusion leading to different chemical profiles.

Between point D and E in Fig. 5 the lower boundary of the pulse-driven convection moves upwards, and at point E the convection zone (and therefore surface convection) vanishes at all. Overall, the convection zone exists for ≈ 1200 yrs, and for ≈ 150 yrs it extends up to the surface. Beyond point E the contraction of the inner regions of the hydrogen shell resumes, while the surface layers react by expansion, resulting in a redward motion in the HRD bringing the He-WD almost back to the RGB region. Finally, contraction seizes the surface layers and the star evolves back to higher effective temperatures towards the cooling branch again.

Around point F just before re-entering the cooling branch, the so-called subflashes develop. Here, contraction initiates another small increase of L_{Hyd} to $\approx 30 \dots 200 L_\odot$ (compared to $\approx 10^5 L_\odot$ during the major flash) leading to a temporary expansion of the outer layers of the star and only minor circle-like excursions in the HRD.

For illustration, Fig. 8 shows the evolution (arbitrary zero point) of the luminosity contribution due to hydrogen burning, L_{Hyd} , and the gravothermal luminosity, L_g , during the flash phase of the $M = 0.234 M_\odot$ sequence. The large plot shows the evolution of the first subflash episode of the first hydrogen flash phase and the small inlet that of the second phase. The peak at $t \approx 0.4512 \cdot 10^7$ yr which is not resolved within the plot range comes from the major flash, the second peak at $t \approx 0.4518 \cdot 10^7$ yr with $L_{\text{Hyd,max}} \approx 250 L_\odot$ followed by a

short period with $L_g < 0$, i.e. expansion, marks the subflash. This first subflash is then followed by another slight increase in L_{Hyd} at $t \approx 0.4528 \cdot 10^7$ yr with $L_{\text{Hyd,max}} \approx 20 L_\odot$ causing the little circle in the track at $\log L/L_\odot \approx 1.2$ (see Fig. 4).

Fig. 7. Evolution of surface and hydrogen luminosity, L and L_{Hyd} , and the contributions due to CNO cycling and pp-burning as a function of cooling age for $M = 0.234 M_\odot$. The figure shows the age range where the hydrogen shell flashes develop. Age $t = 0$ is given by the first turning point after the track has entered the cooling branch (see point A in Fig. 5) and corresponds to a post-RGB age $t_{\text{post-AGB}} \approx 4.62 \cdot 10^7$ yr.

Fig. 8. Evolution of L_{Hyd} (dashed line) and L_g (solid line) as a function of time for the $0.234 M_\odot$ sequence during flash phase: Large plot: First flash phase; inlet: second flash phase (same plot labels). For the definition of $t = 0$ see Fig. 7.

After the second major flash (again unresolved in the time range of this diagram at $t \approx 2.2757 \cdot 10^7$ yr) a local maximum in L_{Hyd} with $L_{\text{Hyd,max}} \approx 30 L_\odot$ and slight expansion is found at $t \approx 2.2762 \cdot 10^7$ yr (i.e. about $5 \cdot 10^3$ yr after the main

flash) corresponding to the small loop in the evolutionary track at $\log L/L_\odot \approx 1.5$.

As previously mentioned the instability in He-WDs is caused by the fading CNO-luminosity on the cooling branch around $T_{\text{eff}} \approx 22000 \dots 25000$ K. After pp-burning became the dominant contribution of hydrogen burning, L_{CNO} again increases on a typical timescale of a few 10^6 to 10^7 yr. Figure 7 shows the situation for the two hydrogen flashes occurring for $M = 0.234 M_\odot$. Beyond $t \approx 4.6 \cdot 10^7$ yr and $t \approx 5.6 \cdot 10^7$ yr L_{CNO} rises again from $L_{\text{CNO}} \approx 0.1$ to a few $10^2 L_\odot$. With ongoing unstable burning the outer layers of the He-WD expand and slightly cool the shell so that L_{CNO} drops again. The peaks in L_{Hyd} ($\approx 10^5 L_\odot$) are due to pp-burning.

To investigate the dependence of the mass on the occurrence of hydrogen flashes we applied the criteria for unstable burning discussed in Sect. 2.1. As already seen in Fig. 6 the degeneracy in the hydrogen shell is quite moderate but far from being negligible. We used the criterion of Kippenhahn & Weigert (1990) to account for the possible effect of degeneracy. The criterion states that nuclear burning in a shell at radius R_{shell} and of thickness ΔR becomes unstable if

$$1 - \nabla_{\text{ad}} \cdot \frac{4\delta}{4\alpha - \frac{R_{\text{shell}}}{\Delta R}} > 0 \quad (1)$$

∇_{ad} is the adiabatic temperature gradient and α and δ are given by $\alpha = \left(\frac{\partial \ln \rho}{\partial \ln P} \right)_T$ and $\delta = - \left(\frac{\partial \ln \rho}{\partial \ln T} \right)_P$. For comparison, we also used the criterion of Schwarzschild & Härm (1965) which predicts unstable burning if

$$\frac{\Delta T}{T_{\text{shell}}} > \frac{4}{\nu} \quad \text{and} \quad \frac{\Delta R}{R_{\text{shell}}} < \frac{5}{2} \cdot |Q| \quad (2)$$

with $Q \approx -8 \dots -4$ and ΔT being the temperature difference between lower and upper shell boundary. A main problem when dealing with these criteria is the definition of quantities as, for example, representative temperatures and pressures in the shell or the typical radial extent of the shell.

However, although we find the instability criterions to be fulfilled in several models the strict application of the aforementioned criteria alone cannot explain the restricted mass range for the occurrence of hydrogen flashes. Some general aspects on the model properties important for the study of unstable burning can be seen from Fig. 9 where different quantities of layers at maximum energy generation are shown along the cooling branch evolution for the non-flash sequences with $M = 0.195$ and $0.414 M_\odot$ and the flash sequence with $M = 0.259 M_\odot$ covering most of the He-WD mass range.

As seen before for $M = 0.234 M_\odot$, degeneracy of the shell layers is moderate (lower left panel) in the upper part of the cooling branch evolution. For $M = 0.259 M_\odot$, $\psi \approx -0.5 \dots 0$ at the beginning of unstable burning ($t \approx 2 \cdot 10^7$ yr). For $M = 0.414 M_\odot$ degeneracy is slightly lower ($\psi \approx -1$, $t \approx 2 \cdot 10^5$ yr) at the corresponding evolutionary stage, and for $M = 0.195 M_\odot$ slightly higher ($\psi \approx 0 \dots +0.5$, $t \approx 5 \cdot 10^8$ yr). For an ideal, non-relativistic gas one obtains for the non-degenerate limiting case $\alpha = \delta = 1$, whereas strong degeneracy ($\psi \gg 1$) leads to $\alpha \approx \frac{3}{5}(1 + \frac{\mu_e}{\mu_0} \frac{1}{\psi})$ and $\delta \approx \frac{3}{2} \frac{\mu_e}{\mu_0} \frac{1}{\psi}$

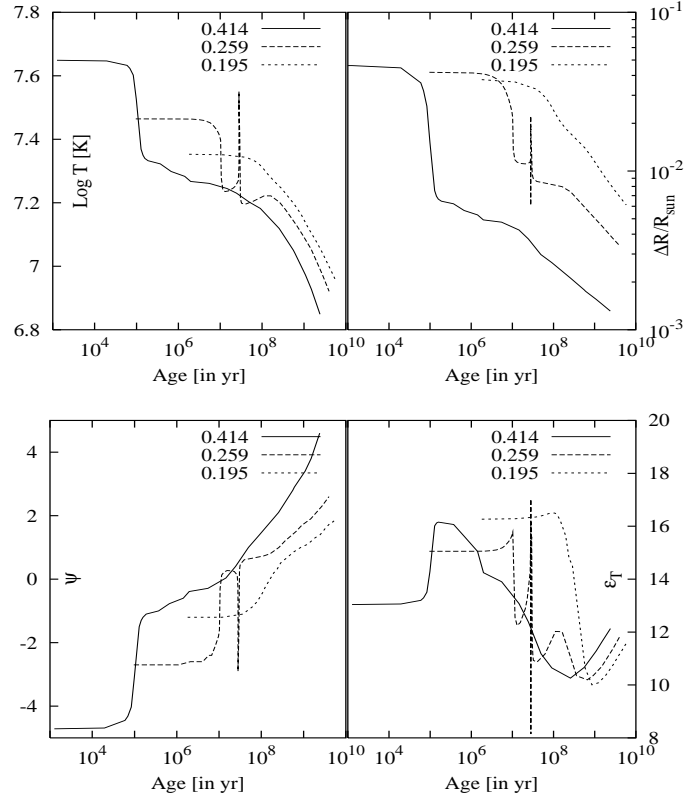

Fig. 9. Different quantities as a function of $t_{\text{post-RGB}}$ for the sequences with $M = 0.195$ and $0.414 M_\odot$ (no flashes) and $M = 0.259 M_\odot$ (one flash): Upper left: Temperature at the maximum of energy generation, ϵ_{max} , in the hydrogen burning shell. Upper right: Radial extent of the hydrogen burning shell. Lower left: Degeneracy parameter ψ at $\epsilon = \epsilon_{\text{max}}$. Lower right: Temperature derivative of the energy generation rate, ϵ_T , at $\epsilon = \epsilon_{\text{max}}$.

with μ_0 and μ_e being the mean molecular weights per ion and electron, resp., (see Kippenhahn & Weigert 1990)³. Thus, inspecting Eq. (1), from ψ alone we would conclude that, if at all, degeneracy favours hydrogen shell flashes for lower He-WD masses.

The temperature sensitivity of nuclear burning along the cooling branch can be seen from the quantity $\epsilon_T = \partial \ln \epsilon / \partial \ln T (= \nu \text{ for } \epsilon \propto T^\nu)$ which is shown in the lower right panel of Fig. 9. When the flash develops for $M = 0.259 M_\odot$, one finds $\epsilon_T \approx 12.5$. For the other masses we have $\epsilon_T \approx 15$ ($M = 0.414 M_\odot$) and $\epsilon_T \approx 11$ ($M = 0.195 M_\odot$). Because unstable nuclear burning is favoured for higher temperature sensitivity of the burning (see Eq. (2)) the occurrence of flashes is favoured for heavier white dwarfs. Thus, combining the effects of degeneracy and large temperature exponents in the energy generation rate might, in principle, explain why high and low-mass He-WDs do not suffer from hydrogen flashes.

³ Note that radiation pressure is negligible and ∇_{ad} does not depend on ψ in the non-relativistic regime.

However, it is most likely the radial thickness of the shell (see upper right panel in Fig. 9) which has the most important effect on the occurrence of hydrogen flashes. At the onset of unstable burning we found $\Delta R \approx 10^{-2} R_{\odot}$ for $M = 0.259 M_{\odot}$ (the shell's borders are taken at the point with $\epsilon = 10^{-3} \cdot \epsilon_{\max}$). For $M = 0.195 M_{\odot}$, ΔR is approximately a factor of two larger and for $M = 0.414 M_{\odot}$ a factor of two smaller. For low-mass He-WDs degeneracy of the shell is of minor importance. Also, the thickness of the shell is too large as to allow hydrogen shell flashes. On the other hand, for high-mass He-WDs the shell is so thin that the thermal cooling time is smaller than the typical time scale for the onset of the instability. Hence, for He-WDs with $M \gtrsim 0.3 M_{\odot}$ an instability might be initiated but the fast cooling of the shell prevents a hydrogen flash (see also next section).

4.3. Final cooling

After the He-WD models with $M = 0.234 M_{\odot}$ and $0.259 M_{\odot}$ have completed their major hydrogen flashes a final onset of a flash results in a local hook in the cooling track (see Figs. 4 and 5, point G). Again this increase of luminosity due to hydrogen burning is caused by CNO cycling. This can be seen from Figs. 10 and 11 where the evolution of different luminosity contributions for the two flash sequences are plotted as a function of $t_{\text{post-RGB}}$ for the whole post-RGB evolution.

Fig. 10. Evolution of different luminosity contributions (see plot labels) as a function of $t_{\text{post-RGB}}$ for the sequence with $M = 0.234 M_{\odot}$: L_{pp} : luminosity due to pp-burning; L_{CNO} : luminosity due to CNO cycling; L_{Hyd} : complete luminosity due to hydrogen burning; L : surface luminosity; L_g : contribution of gravothermal luminosity due to contraction ($L_g > 0$); L_N luminosity contribution due to neutrino losses. $t = 0$ is adopted as in Fig. 3 (see also Fig. 7 for $t = 3 \dots 8 \cdot 10^7 \text{ yr}$).

L_{CNO} shows a local maximum at $t_{\text{post-RGB}} \approx 1.23 \cdot 10^8 \text{ yr}$ for $M = 0.234 M_{\odot}$, approximately $5 \cdot 10^7 \text{ yr}$ after the last major flash. The corresponding point for $M = 0.259 M_{\odot}$ is at an age of $t_{\text{post-RGB}} \approx 1.40 \cdot 10^8 \text{ yr}$, which is about 10^8 yr after

Fig. 11. Same as Fig. 10, but for the $M = 0.259 M_{\odot}$ sequence.

the major flash. At this point of evolution hydrogen shell burning is already dominated by pp-burning ($L_{\text{pp}} \approx 20 \cdot L_{\text{CNO}}$), but the difference between both contributions is rather small compared to the later evolution (see Figs. 10 and 11 for $t \gtrsim 1 \text{ Gyr}$). Because the characteristic cooling time is now smaller than the typical timescale for the onset of unstable burning another strong hydrogen flash is prevented. Such onsets of unstable CNO-burning have also been found in the sequences with $0.300 M_{\odot}$ and $0.331 M_{\odot}$, resulting in similar hooks on the cooling track (see Fig. 1 in Paper I).

The further evolution in both flash sequences is comparable to the one without hydrogen flashes (see for instance Fig. 4 in Paper I). It is characterized by quiescent hydrogen shell burning via the pp-chains until an age of about 10 Gyr. Then hydrogen burning terminates and contraction determines the surface luminosity evolution and final cooling (see Figs. 10 and 11).

Finally, we like to note that the mass-radius-relation of He-WDs is only affected by hydrogen shell flashes for $T_{\text{eff}} \approx 20000 \dots 25000 \text{ K}$: The high burning rates associated with the flashes lead to a higher envelope consumption compared to sequences without flashes, resulting in slightly smaller radii and enhanced evolutionary speeds on the upper part of the cooling branch. Besides, since the timescale of the instabilities is short compared to the characteristic cooling time (a few 10^7 yr compared to Gyr) and most of the time during a flash is spent close to the cooling branch, the influence of hydrogen shell flashes on the mass-radius-relation is restricted to the onset phase where the changes in radius are moderate.

4.4. Roche lobe overflow during the flashes

During the hydrogen shell flashes the expansion of the outermost layers (from a few 0.01 solar radii to a few solar radii) forces the He-WDs to evolve back into the RGB domain in the HRD (see Figs. 4 and 5). Due to the binary nature of He-WDs, in principle, mass transfer to a companion (in most cases another white dwarf or a pulsar) should be taken into account in this particular evolutionary phase. This has been considered,

for instance, in the calculations of Iben & Tutukov (1986) leading to a significant removal of envelope matter and a faster exhaustion of hydrogen burning.

Besides the sequences already discussed we thus also investigated the evolution of the flash model sequence with $M = 0.259 M_{\odot}$ considering high mass-loss episodes due to Roche lobe overflow. Because we were only interested in the general influence on the final cooling properties of our models we used a rather simple algorithm to account for Roche lobe overflow from the He-WD to a companion: For a given Roche radius R_{Roche} (in our case 2, 3 and 5 R_{\odot}) and actual model radius R , we increased η in the Reimers mass loss formula by a factor of $2 \cdot R/R_{\text{Roche}}$ for $R > R_{\text{Roche}}$. Otherwise, η was set to its standard value of 0.5 used for all post-RGB calculations.

Figure 12 presents the evolutionary tracks in the HRD during the flash for $M = 0.259 M_{\odot}$ and different assumptions of the Roche radius. The models quickly reach the line with $R = R_{\text{Roche}}$. For comparison, also the track without Roche-lobe overflow is shown. During the adjustment phase, after the models have passed $R = R_{\text{Roche}}$, mass-loss rapidly rises up to $\dot{M}_{\text{high}} \approx 10^{-3} M_{\odot}/\text{yr}$ and forces the models to evolve back to $R \approx R_{\text{Roche}}$. Finally, $\dot{M} \approx 5 \cdot 10^{-6} M_{\odot}/\text{yr}$ when the models evolve along at $R \approx R_{\text{Roche}}$. When Roche lobe overflow ends ($R < R_{\text{Roche}}$) mass loss has dropped to $\dot{M} = \dot{M}_{\text{Reimers}} \approx 10^{-11} M_{\odot}/\text{yr}$.

After the end of Roche lobe overflow and the subflash phase the tracks rapidly merge with the one calculated without Roche lobe overflow at the beginning of final cooling evolution. As Fig. 12 shows the subflash excursion is the less pronounced the smaller R_{Roche} .

The convergence of the tracks shows that the cooling properties of He-WD models are not seriously affected by the Roche lobe events because similar tracks imply similar radii and thus similar envelope masses which determine the cooling evolution due to hydrogen burning. This is confirmed by Figs. 13, 14 and 15. In Fig. 13 the evolution of the envelope mass, M_{env} , is given as a function of T_{eff} for the tracks from Fig. 12, in Fig. 15 the corresponding evolution of surface luminosity as a function of $t_{\text{post-RGB}}$ is plotted. Figure 14 shows the reduction of envelope mass for all sequences as a function of $t_{\text{post-RGB}}$ close to $R = R_{\text{Roche}}$ and beyond. Figures 13 and 14 indicates that $\sim 6 \cdot 10^{-4} M_{\odot}$ of the envelope mass is lost in the non-Roche model during the flash phase (taken from the first local maximum in T_{eff} to the last one). Note that the temporal increase of M_{env} in Fig. 13 comes from the pulse driven convection zone by mixing hydrogen-rich material somewhat below the layers with $X = 0.35$ which determine the border between core and envelope (cf. Fig. 6).

A significant reduction of M_{env} sets in when dominant hydrogen burning has again established at the end of the subflash phase (see Fig. 13 at $T_{\text{eff}} \approx 27000$ K and Fig. 14 for $2.81 \lesssim t/10^7 \text{ yr} \lesssim 2.95$). This envelope reduction is slowed down when the model enters the cooling branch (see Fig. 13 at $T_{\text{eff,max}} \approx 33000$ K and Fig. 14 for $t \gtrsim 2.95 \cdot 10^7 \text{ yr}$). The envelope is eroded by mass loss and shell burning. This can be written as $\dot{M}_{\text{env}} = \dot{M}_{\text{wind}} + \dot{M}_{\text{core}}$ with the mass loss

rate \dot{M}_{wind} and the core growth rate \dot{M}_{core} . The core growth rate is given by $\dot{M}_{\text{core}} = \frac{L_{\text{Hyd}}}{X \cdot E_{\text{H}}}$ with the hydrogen content X and the gain of energy due to hydrogen burning per mass unit, $E_{\text{H}} \approx 6.3 \cdot 10^{18} \text{ erg g}^{-1}$.

For sequences without Roche-lobe overflow \dot{M}_{env} is mainly determined by shell burning, i. e. $\dot{M}_{\text{env}} \approx \dot{M}_{\text{core}}$. With a mean value of $L_{\text{Hyd}} \approx 30 L_{\odot}$ and $X \approx 0.7$ it is $\dot{M}_{\text{core}} \approx 4.3 \cdot 10^{-10} M_{\odot} \text{ yr}^{-1}$. With $\Delta t \approx 1.3 \cdot 10^6 \text{ yr}$ (see Fig. 14) one obtains $\Delta M_{\text{env}} \approx \dot{M}_{\text{core}} \cdot \Delta t \approx 5.6 \cdot 10^{-4} M_{\odot}$ in good agreement with the value obtained from Figs. 13 and 14.

For sequences with Roche-lobe overflow the situation is different. Here, the consumption of envelope mass occurs preferentially due to the high mass-loss phase when the models are close to their Roche limit ($T_{\text{eff}} \approx 8000 \dots 15000$ K, see Fig. 13). For instance, for the sequence with $R_{\text{Roche}} = 3 R_{\odot}$ it is $\Delta M_{\text{env}} \approx 4.5 \cdot 10^{-4} M_{\odot}$, corresponding to a mean mass loss of $\dot{M}_{\text{wind}} \approx 10^{-5} M_{\odot} \text{ yr}^{-1}$ lasting for $\Delta t \approx 40 \text{ yr}$. Afterwards M_{env} is further reduced by $\Delta M_{\text{env}} \approx 2 \cdot 10^{-4} M_{\odot}$ due to nuclear burning (see Fig. 14).

Fig. 13. Evolution of M_{env} as a function of T_{eff} for tracks with $M = 0.259 M_{\odot}$ and different Roche radii (see labels). The smaller R_{Roche} the faster M_{env} is reduced, but when the star is back on the cooling branch the residual envelope mass is almost the same for all Roche tracks as it is for the non-Roche lobe track.

In the end, the envelope masses are almost the same when the different models enter the final cooling branch ($M_{\text{env}} \approx 2.05 \cdot 10^{-3} M_{\odot}$, see Fig. 14), i.e. the residual envelope mass and the corresponding cooling evolution are rather independent from the evolutionary history.

On one hand, the latter result is consistent with the results of Iben & Tutukov (1986). In the case of Roche lobe overflow the high mass loss determines the evolutionary speed, whereas otherwise the evolution is characterized by the thermal timescale of the envelope. On the other hand, in their $0.298 M_{\odot}$ model the high mass loss causes a considerable loss of envelope mass ($\approx 1.5 \cdot 10^{-3} M_{\odot}$) and prevents hydrogen burn-

Fig. 12. HRD with tracks for $M = 0.259 M_{\odot}$ and different Roche radii (2, 3 and 5 R_{\odot}). For $R \geq R_{\text{Roche}}$ mass loss was adjusted as to provide $R \approx R_{\text{Roche}}$ as long as the star does not evolve back to the white dwarf domain. Lines of constant radius are also plotted. The arrows indicate the course of evolution. The inset in the lower right corner is a blow-up of the part close to the Roche radii.

ing from becoming ever dominant again. Consequently, their model cools down quite rapidly. The cooling time is of the order of a few 10^8 yr whereas our models are controlled by residual hydrogen burning leading to cooling times of the order of Gyr (see Figs. 10 and 11).

Thus, from our calculations it appears that different mass loss histories during the phase of the hydrogen shell flashes do not influence the final cooling of He-WDs significantly. This result seems to be consistent with the calculations of Kippenhahn et al. (1968): Their $M = 0.264 M_{\odot}$ model evolves through one major hydrogen shell flash and one strong sub-flash, both bringing the white dwarf radius above the critical Roche radius (points Q to R and T to U in their Fig. 1), resulting in a total mass loss of about $10^{-3} M_{\odot}$ which is comparable to the $6 \cdot 10^{-4} M_{\odot}$ of the present calculation with only one high mass-loss episode. After a rapid evolution back to the cooling branch the evolution is slowed down, and at $\log(L/L_{\odot}) \approx -2$ (point W in their calculation) a cooling age of approximately 2.55 Gyr is reached, comparable with our $M = 0.259 M_{\odot}$ model which has at the same position $t_{\text{post-RGB}} \approx 1.85$ Gyr. On the other hand, by assuming a linear correlation between $\log L/L_{\odot}$ and $\log t_{\text{cool}}$ as a first approximation, the cooling age

of the model of Iben & Tutukov (1986) can be estimated to be only $t_{\text{cool}} \approx 2.3 \cdot 10^8$ yr at $\log(L/L_{\odot}) \approx -2$ (using their points S and T, see their Fig. 1 and Table 1). This value is almost one order of magnitude below the one given by models which allow hydrogen burning to continue.

5. Summary

We have calculated evolutionary models of low-mass white dwarfs with helium cores to study in detail their cooling behaviour and their evolution including phases of thermally unstable hydrogen burning (hydrogen shell flashes). We found that the occurrence of these thermal instabilities is restricted to the mass range $0.21 \lesssim M/M_{\odot} \lesssim 0.3$. It is noteworthy that a sufficient temporal resolution is essential to avoid numerical fluctuations in the energy output of the shell during early cooling branch evolution.

The flashes occur during the fast cooling of the shell at the beginning of the cooling branch evolution. This especially affects the lower part of the shell region where CNO cycling is the dominant contribution to hydrogen burning. CNO-burning is temperature sensitive enough to cause thermal instabilities

Fig. 14. Evolution of envelope mass as a function of $t_{\text{post-RGB}}$ for tracks with $M = 0.259 M_{\odot}$ and different Roche radii (see labels). The plot shows the reduction of M_{env} during and immediately after Roche-lobe overflow. The inset shows the evolution of M_{env} on a larger scale.

Fig. 15. Evolution of surface luminosity L as a function of $t_{\text{post-RGB}}$ for tracks with $M = 0.259 M_{\odot}$ and different Roche radii (see labels). The models suffering a high mass-loss episode show the same cooling behaviour as the non-Roche sequence. The inset shows the evolution of L during the subflash phase.

if two conditions are fulfilled: The shell is thin enough (this is obviously not the case for $M/M_{\odot} \lesssim 0.21$) and the cooling time is large enough as to avoid an extinction of the shell before the instability is fully established (this does not hold for $M/M_{\odot} \gtrsim 0.3$). The final cooling is not affected from possible flash events, i.e. hydrogen shell burning establishes again as dominant energy source at the end of the flash episode as in the case of non-flash models.

This result also holds when Roche-lobe overflow of the He-WD to a companion is considered during the expansion into the RGB regime. One of the main features related to hydrogen shell flashes is the change of envelope composition due to a pulse-driven convection zone which temporarily extends to the outermost layers of the star. The resulting drop in hydrogen is $\Delta X \approx 0.06$.

While the typical duration of a hydrogen flash is short compared to the cooling time of He-WDs (10^7 yr compared to Gyr) and He-WDs evolve close to their cooling tracks for most of the time during a flash, the influence of these unstable phases on the mass-radius-relation of helium white dwarfs is moderate and restricted to effective temperatures of 20000 . . . 25000 K.

Appendix A: Remarks on the appropriate temporal resolution

The question of sufficient resolution always arises when one deals with instabilities in evolutionary models. As mentioned in Sect. 2.2 thermal instabilities in He-WD model calculations can obviously be missed if too large time steps are used. Large time steps may also cause fluctuations in the shell energy output.

Fig. A.1. Hertzsprung-Russell diagram for an evolutionary track with $M = 0.195 M_{\odot}$ and different temporal resolutions (see labels). The upper left panel shows the final track with the appropriate resolution giving a smooth course of the hydrogen luminosity contribution L_{Hyd} (see Fig. A.2). For the other tracks deviations caused by local fluctuations in L_{Hyd} (see Fig. A.2) increase with increasing maximum allowed time step.

The four panels in Fig. A.1 show a part of the evolutionary track of our He-WD model with $M = 0.195 M_{\odot}$ in the vicinity of the turn-around point, $T_{\text{eff}} = T_{\text{eff,max}}$ with different temporal resolution. The corresponding evolution of the luminosity contribution due to hydrogen shell burning, L_{Hyd} , is shown in the four panels of Fig. A.2.

The track with sufficient temporal resolution (upper left panel in Fig. A.1, $\Delta t_{\text{max}} = 2 \cdot 10^4 \text{ yr}$) shows no perturbations due to fluctuations in the shell energy production (smooth curve in Figs. A.1 and A.2). When the maximum time step is increased to $\Delta t_{\text{max}} = 5 \cdot 10^4 \text{ yr}$ small perturbations occur in L_{Hyd} and in the track (for $-0.4 \lesssim \log L/L_{\odot} \lesssim -0.25$, see upper right panel in Fig. A.1). When the maximum time step is further increased by a factor of 2 (lower left panel in Figs. A.1 and A.2) the fluctuations in L_{Hyd} and in the track are much more prominent but the evolution stabilizes after a final hook in the track at $\log L/L_{\odot} \approx -0.5$. In this case the shape of the tracks corresponds with those of e.g. Webbink (1975) or Sarna et al. (1998). Finally, for $\Delta t_{\text{max}} = 5 \cdot 10^5 \text{ yr}$ the calculations became numerically unstable.

Therefore, we selected $\Delta t_{\text{max}} \lesssim 2 \cdot 10^4 \text{ yr}$ as the maximum time step for our calculations. Additionally, to handle the large local changes in the luminosity budget of the models we cou-

pled the evolutionary time step to changes in L_{Hyd} by reducing Δt_{max} by a factor of 2 if L_{Hyd} changes by more than 5 %.

Fig. A.2. Evolution of the luminosity contribution due to hydrogen shell burning (L_{Hyd}) for $M = 0.195 M_{\odot}$ with different temporal resolution (see also Fig. A.1).
